Abstract: In order to create a good 3D reconstruction from an image, shape information of the object of interest is needed. One way to acquire it is based on the shading information. This can be solved using the Shape from Shading method. Unfortunately this method has some drawbacks, namely the depth ambiguity problems. Two points which have the same intensity will have the same depth, although in reality they have different depth. Color also plays an important role. Some color generates higher intensity than the others. This makes the resulting output of the system to reconstruct the object incorrectly. We propose a color segmentation based depth adjustment to overcome this problem. First we cluster the image into color clusters. Based on this color cluster we will adjust the depth of vertices belonging to the higher intensity cluster accordingly. The proposed method can reduce the effect of the depth ambiguities.

Keywords: shape from shading, color segmentation, single view reconstruction.

Introduction

3D reconstruction from image has long been studied in the field of computer vision. Based on the number of input images, 3D reconstruction can be separated into two types: a single input image and multiple input images. Multiple input images reconstruction can reconstruct object in a more detail results, but suffers from rectifying and correlation problems. Multiple images taken from multiple angles are also required to get a good reconstruction, which makes it inconvenient to use. On the other hand, a single input image will be much easier for the user to use. The challenge of a single input system is limited information regarding the overall shape of the object to be reconstructed. Given an image of an object, human can determine the overall shape of the object. One of the clues in shape perception can be acquired through shading information. Shape from shading (SFS) uses the intensity information of an image to approximate the shape. Unfortunately, SFS has some drawbacks, which are the depth ambiguity problems. One of these problems is some parts of the object in the image which have same intensity value will have the same depth. Another problem is regarding the color intensity.

In order to solve these problems, we propose an algorithm based on the color segmentation method. First we divide the image into several color cluster based on its color intensity. Then, we adjust the depth of the surfaces belonging to the higher intensity cluster to reduce the color intensity influence. Finally in order to make the final output smoother, some simple smoothing operation is done.

Related Work

As already mentioned in the previous part, human uses some clues in order to perceive the shape of an object. SFS is a branch of Shape from X method, which uses these clues to mime how people perceive an object and then reconstruct an object from the input image. Depending on the input of the algorithm, X can be anything from, but no limited to, texture, shading, etc.

SFS was first developed by Horn. SFS is used to derive 3D scene description from one or more 2D images [1]. The main input for SFS is the intensity value of the input images, which usually can be retrieved from the gray level of the input image. Lambertian surface, orthographic projection and known light source position are some of the assumptions usually used in solving SFS problems.

Similar with our method, [12] also uses color information in order to improve the SFS algorithm. First, they use a chromaticity-based specular reflection removal algorithm to make a pure diffuse image of the object of interest. Then they apply some color adjustment to generate an image without surface changes, which will be used as the input of the SFS algorithm. Interested reader can also refer to survey papers [1] and [13] for more details regarding SFS algorithms.

As we know, some color generates more intensity than the others. Most of the paper mentioned above does not consider color influence to the intensity values which actually has an effect to the reconstructed object. Therefore, we would like to address this problem.

### Problems Description

As mentioned in the beginning of this paper, shape from shading suffers from some drawbacks. Consider Fig.1. A through E are five points on the surface of the object (a sphere cut by a plane) and $N_A$, $N_B$, $N_C$, $N_D$, and $N_E$ are the normal direction of each point. Assume that the light source position has the same position with the camera position.

Since shape from shading assumes Lambertian surface model, the intensity captured by the camera will follow (1).

$$ I_c = I_i \cos \theta_i. $$

As can be seen, point A, C, and E will have the same intensity value captured by the camera although they have different depths. The reason is because they have the same normal direction, which will make (1) have exactly the same value. This will make point A, C, and E reconstructed with the same depth value or has many interpretation such as illustrates in Fig.2.

Another depth ambiguity arises because of the color information. Some colors generate higher intensity compared to other colors. Consider Fig. 3. As can be seen, the words part of the input image, since they have yellow color, generate a higher intensity compared to the background (red). This characteristic will influence the depth approximation, which will make an incorrect result. Fig.4 is the rendered image using only (1).

![Figure 1. Surface example of a sphere and a plane](image1.png)

![Figure 2. Multiple interpretations of a surface](image2.png)
In this part, we will explain our proposed method. There are some steps in our method (refer to Fig. 5). The first step is to make base meshes. This is done in order to reduce the area to be computed and to make sure that the object of interest will be able to be reconstructed completely.

Before explaining the steps in more detail, there are some assumptions used in this paper. First is the input image for the proposed method. The object of interest of the input images used in this paper is assumed to have been extracted from the background. An example of the input image can be seen in Fig. 5. We also assume that the light source has the same position as the camera position. Intensity value will also be considered to be the depth of the surfaces.

A. Contour Detection
This is done by using Canny Edge detection[14]. Some parts might be erased during the extraction, such as small portions of the whiskers part in Fig. 6, therefore we also add dilation method to fill in the missing part. Next, we keep only the external contour data. Fig. 7 illustrates this step.

B. Vertex Generation
Contour data from the previous step is a set of points. In order to simplify the contour data which will be the base for the mesh generation step, we use the Douglas Peucker algorithm. We also add vertices inside the contour by using the grid method. The distance between one point with the others on the grid is 10. Fig. 8 illustrates the output of this step.

C. Mesh Generation
In order to generate the mesh, similar with [3], triangular mesh is created. This is done using constrained delaunay triangulation. The output vertices of the Douglas Peucker algorithm will be considered to be the constraint. This means, no triangles will be generated if it lies outside the external contours. The resulting output of this step can be seen in Fig. 9.
D. Depth Extraction

This step is the heart of our proposed method. In order to extract the depth information, intensity value of the input image is used. Intensity value might be acquired from the grey value of the input image (RGB), but this will raise a problem mentioned in the problem description section. Therefore, we use the grey level image taken from HSV color space, particularly the V as the intensity value, rather than the grey level of RGB color space.

Fig. 10 compares the grey image of the input image in RGB color space and HSV color space. As can be seen, horns, whiskers and stomach part of the object, which have yellow colour, generate higher intensity in RGB color space. On the contrary, HSV color space produces better output in terms of intensity (horns part and face part are blend equally).

Two steps are done in depth extraction step: the flat region search and the cutting algorithm (depth adjustment).

- Flat Region Search

This is done in order to reduce the effect of the depth ambiguity. First, we determine whether a triangle mesh represents a flat surface or not. This is done by checking each vertex of the triangles whether they have the same intensity value or different intensity value. A triangle which has three identical intensity values at each vertex is considered to represent a flat area. See Fig.11.
Let triangle ABD and BCD be two adjacent triangles. There are two interpretations of these triangles. One can be seen on the upper part of Fig.11 and another on the bottom part of Fig.11. \( n_1 \) and \( n_2 \) are the normal directions of each triangle respectively. By looking at the normal direction of the triangles, we can determine whether these two triangles combine into a flat surface or non-flat surface. Again, based on (1) the intensity value of a triangle will depend on its normal direction, and therefore, by searching for adjacent triangles which have the same intensity will give us an intuition whether they create a flat surface or not.

Then, we group vertices which have the same intensity. We then find vertices which were connected directly with the other vertices that do not have the same intensity. This step can be summarized in the following algorithm:

- For every vertex do:
  - Check the neighbors
  - If neighbor has the same intensity, do nothing
  - Else, keep the neighbor’s intensity value
- If all vertices have been examined, calculate the average of the intensity values that were kept.

Finally, all vertices belonging to the same intensity group will have the average intensity kept as the new depth.

- **Cutting algorithm (depth adjustment)**

Before doing the cutting algorithm, we divide the input image into 3 color clusters. This is done using k-means clustering method with k value equals 3. This step is required for the next step, where we will reduce the depth of each vertex according to its color clusters. Fig.12 illustrates the output of k-means color clustering.

Next, we reduce the depth (intensity) of each vertex belonging to the higher intensity color cluster. As mentioned before, yellow color has higher intensity than red color. Therefore, we will reduce vertices’ depth belonging to the yellow color cluster. This is done by firstly calculating the average difference of intensity between the vertices on the higher intensity group (yellow) and the other vertices which have direct connections with the higher intensity group. Fig. 13 illustrates this step.
Point A, B, E, and F belong to the lower intensity cluster. Point C and D belong to the higher intensity cluster. Δ can be defined as follows:

$$\Delta = \sum_{i,j} I_{ij}$$

where:

- $$I_{ij} = \begin{cases} \|I_i - I_j\| & \text{if there is connection between } i \text{ and } j \\ 0 & \text{otherwise} \end{cases}$$

- $$n = \text{number of paired } ij \text{ vertices connected with each other}$$

It should be noted that (2) only apply to pairs with different clusters. For example, point A and point B will not be considered for calculating Δ even though there is a connection from point A to point B (Fig. 12, illustrated with line connecting those points) and so do point C and D, point E and F. Only B-C pair and D-E pair will be considered when calculating Δ.

After calculating the average difference, every vertex belonging to the higher intensity cluster will be reduced with Δ. Continuous line in Fig.12 illustrates output generated from this step. See that the depth of point C and D are reduced with Δ. Final step in this method is to smooth the last reconstruction. This is done by applying the median filter. A search circle is applied to every vertex, where the vertex of interest will be the center of the search circle. Every vertex lying inside the radius of the circle will be considered to be chosen as the final depth for the vertex of interest. The median value of the vertices lying inside the circle will be the final depth for the vertex of interest.

**Result**

The proposed method was implemented in C language, OpenCV library support, OpenGL library support, and Triangle [15] program for applying the constrained Delaunay Triangulation during mesh generation. Size of the images used is 640x480. Twelve input images are used in this paper. See Fig.14. Three of the input images used are artificial images and the rest are natural images. The intensity value of each vertex ranged from 0 to 1, therefore we multiply the value with 100. 50 and 150 are used as the parameters for canny threshold respectively. As for the median filtering, we use 15 for the radius of the circle.

A limitation in our current algorithm is regarding the number of objects to be reconstructed. Currently only one object can be reconstructed using this algorithm. Fully black-colored object will not also be able to be reconstructed correctly.

The result of our proposed method (depth extraction method) is compared with the SFS algorithm as in [2]. Three comparisons are presented as in Fig.15 – Fig.18. As can be seen the proposed method generates a better result, especially for the artificial 2 example (Fig.17). Depth ambiguity in this example can be reduced using the proposed method. Also can be seen from Fig.17, depth ambiguity because of color effect can be reduced.

Two types of depth ambiguities are presented. The first depth ambiguity is due to color effects. Some color generates higher intensity value than the others. This will result in an incorrect reconstruction when we use shape from shading method. The second depth ambiguity is due to the same intensity value. Two points generating same intensity value will be considered to have the same height, although in reality they have different depths. In this paper we propose an algorithm to reduce the effect of both of the ambiguities in shape from shading. Twelve input images are used: three of them are artificial images and the rest are natural images.

By using the proposed method, which utilizes color segmentation and depth adjustment, depth ambiguity of SFS can be reduced as can be seen in result section. First we cluster the input image into some color clusters. The cluster which has highest intensity value will then be reduced (or set) in accordance with the average intensity difference with the lower intensity cluster. Compared to another SFS algorithm, it can be seen that the results are better. In our proposed method, a global depth adjustment is used, which means that depth adjustments are based on the average of the overall color intensity difference. A further research regarding the local depth adjustment will be our main focus.
